Background

Serial screening is critical for restricting spread of SARS-CoV-2 by facilitating the timely identification of infected individuals to interrupt transmission chains. The variation in sensitivity of different diagnostic tests at different stages of infection has not been well documented.

Methods

This is a longitudinal study of 43 adults newly infected with SARS-CoV-2. All participants provided daily samples for saliva and nasal swab RTqPCR, Quidel SARS Sofia antigen FIA, and live virus culture.

Results

We show that both RTqPCR and the Quidel SARS Sofia antigen FIA peak in sensitivity during the period in which live virus is detected in nasal swabs, but the sensitivity of RTqPCR tests rises more rapidly prior to this period. We also estimate the sensitivities of RTqPCR and antigen tests as a function of testing frequency.

Conclusions

RTqPCR tests are more effective than antigen tests at identifying infected individuals prior to or early during the infectious period and thus for minimizing forward transmission (given timely results reporting). All tests showed >98% sensitivity for identifying infected individuals if used at least every three days. Daily screening using antigen tests can achieve ~90% sensitivity for identifying infected individuals while they are viral culture positive.

KEYWORDS: SARS-CoV-2, Diagnostic testing, antigen testing, RTqPCR testing, test sensitivity

Accepted Manuscript

INTRODUCTION:

Frequent rapid diagnostic testing is critical for restricting community spread of SARS-CoV-2 by allowing the timely identification and isolation of infected individuals to interrupt the chain of transmission. Quantitative reverse transcription polymerase chain reaction (RTqPCR)-based detection of viral RNA within nasal swab or saliva samples represents the gold standard for sensitivity in detecting the presence of SARS-CoV-2. Unfortunately, it has been difficult to achieve high testing frequency and volume with the rapid reporting of results needed to mitigate transmission effectively due to supply shortages, cost, and infrastructure limitations.

There is considerable interest in the potential of rapid, lateral flow antigen tests to expand diagnostic testing capacity due to their ease of use, availability, relatively low cost, and rapid time-to-results [1]. However, data for their use in screening asymptomatic individuals is sparse [2]. Enthusiasm for their widespread deployment has been further tempered by well-publicized examples of false positive results in people with low pre-test probability of infection, and by reports suggesting they lack sensitivity compared with RTqPCR, potentially making them less effective at mitigating community spread [3–5].

To maximize the effectiveness of available testing resources, there is an urgent need to quantify the sensitivities of different testing platforms at different stages of infection and define how sensitivity can be enhanced through serial testing. To address this, we compared the sensitivities of nasal and saliva RTqPCR tests with the Quidel Sofia SARS Antigen Fluorescent Immunoassay (FIA) over the course of mild or asymptomatic acute SARS-CoV-2 infection through daily sampling of individuals enrolled early during infection. We also estimated the effects of varying serial testing frequency on the sensitivities of both RTqPCR and antigen tests.

METHODS:

This study was approved by the Western Institutional Review Board, and all participants provided informed consent.

Participants

All on-campus students and employees of the University of Illinois at Urbana-Champaign are required to submit saliva for RTqPCR testing every 2-4 days as part of the SHIELD campus surveillance testing program. Those testing positive are instructed to isolate, and were eligible to enroll in this study for a period of 24 hours following receipt of their positive test result. Close contacts of individuals who test positive (particularly those co-housed with them) are instructed to quarantine and were eligible to enroll for up to 5 days after their last known exposure to an infected individual. All participants were also required to have a documented negative saliva RTqPCR result 7 days prior to enrollment in the study.

Individuals were recruited via either a link shared in an automated text message providing isolation information sent within 30 minutes of a positive test result, a call from a study recruiter, or a link shared by an enrolled study participant or included in information provided to all quarantining close contacts. In addition, signs were used at each testing location and a website was available to inform the community about the study.

Participants were required to be at least 18 years of age, have a valid university ID, speak English, have internet access, and live within 8 miles of the university campus. After enrollment and consent, participants completed an initial survey to collect information on

demographics and health history, including suspected date of SARS-CoV-2 exposure. They were then provided with sample collection supplies.

Participants who tested positive prior to enrollment or during quarantine were followed for up to 14 days. Quarantining participants who continued to test negative by saliva RTqPCR were followed for up to 7 days after their last exposure. All participants' data and survey responses were collected in the Eureka digital study platform.

Sample collection

Each day, participants were remotely observed by study staff collecting:

1. 2 mL of saliva into a 50mL conical tube.
2. 1 nasal swab from a single nostril using a foam-tipped swab that was placed within a dry collection tube.
3. 1 nasal swab from the other nostril using a flocked swab that was subsequently placed in a collection vial containing viral transport media (VTM).

The order of nostrils (left vs. right) used for the two different swabs was randomized. For nasal swabs, participants were instructed to insert the soft tip of the swab at least 1 cm into the indicated nostril until they encountered mild resistance, rotate the swab around the nostril 5 times, leaving it in place for 10-15 seconds. After daily sample collection, participants completed a symptom survey. A courier collected all participant samples within 1 hour of collection using a no-contact pickup protocol designed to minimize courier exposure to infected participants. All study protocols were consistent throughout the duration of the study.

Saliva RTqPCR

After collection, saliva samples were stored at room temperature and RTqPCR was run within 12 hours of initial collection. The protocol for direct saliva-to-RTqPCR assay used has been detailed previously[6]. In brief, saliva samples were heated at 95°C for 30 minutes, followed by the addition of 2X Tris/Borate/EDTA buffer (TBE) at a 1:1 ratio (final concentration 1X TBE) and Tween-20 to a final concentration of 0.5%. Samples were assayed using the Thermo Taqpath COVID-19 assay.

Quidel assay

Foam-tipped nasal swabs were placed in collection tubes, transported with cold packs, and stored at 4°C overnight based on guidance from the manufacturer. The morning after collection, swabs were run through the Sofia SARS antigen FIA on Sofia 2 devices according to the manufacturer's protocol.

Nasal swab RTqPCR

Collection tubes containing VTM and flocked nasal swabs were stored at -80°C after collection and were subsequently shipped to Johns Hopkins University for RTqPCR and viral culture. After thawing, VTM was aliquoted for RTqPCR and infectivity assays. One ml of VTM from the nasal swab was assayed on the Abbott Alinity per manufacturer's instructions in a College of American Pathologist and CLIA-certified laboratory.

Nasal virus culture

VeroTMPRSS2 cells were grown in complete medium (CM) consisting of DMEM with 10% fetal bovine serum (Gibco), 1 mM glutamine (Invitrogen), 1 mM sodium pyruvate (Invitrogen), 100 U/ml of penicillin (Invitrogen), and 100 µg/ml of streptomycin (Invitrogen)[7]. Viral infectivity was assessed on VeroTMPRSS2 cells as previously described using infection media (IM; identical to CM except the FBS is reduced to 2.5%)[8]. When a cytopathic effect was visible in >50% of cells in a given well, the supernatant was harvested. The presence of SARS-CoV-2 was confirmed through RTqPCR as described previously by extracting RNA from the cell culture supernatant using the Qiagen viral RNA isolation kit and performing RTqPCR using the N1 and N2 SARS-CoV-2-specific primers and probes in addition to primers and probes for human RNaseP gene using synthetic RNA target sequences to establish a standard curve[9].

Data Analysis

At the time of analysis, nasal samples from 51 participants had been analyzed by virus culture and RTqPCR. Eight individuals were removed from the analysis because their nasal virus culture was never positive, leaving 43 remaining participants. All confidence intervals around sensitivity were calculated using binconf from the Hmisc package in R version 3.6.2.

The sensitivity of each of the tests was analyzed in three ways:

First, we calculated the “daily sensitivity” of each test across the course of the infection. Daily sensitivity was defined as the ability of each test (antigen, saliva RTqPCR, or nasal RTqPCR) to detect an infected person on a particular day, with day 0 defined as the day of first positive viral culture. Daily sensitivity was not calculated for timepoints with fewer than 5 observed person-days.

Second, we calculated the ability of each test to detect an infected person according to their viral culture status (“status sensitivity”). Viral culture status was defined as “pre-positive” on days prior to the first positive viral culture result, “positive” on days for which viral culture results were positive, and “post-positive” on days with negative viral culture results that occur after the first positive culture result. Status sensitivity was defined as the proportion of person-days with a positive result.

Finally, we calculated the ability of repeated testing over a 14-day period to detect an infected person (“protocol sensitivity”) using a value-of-information approach. Seven different testing frequencies were considered: daily, every other day, every third day, and so on, up to weekly sampling. For each individual, the result of testing on a given schedule was calculated for each potential starting date, with test results interpreted in parallel (all tests must be negative to be considered negative). For instance, each person contributed two observations to the “every other day” schedule, one starting on the first day of the study and comprising samples from days 1, 3, 5, 7, 9, 11, and 13, and the other starting on the second day of the study and comprising samples from days 2, 4, 6, 8, 10, 12, and 14. As each testing schedule was evaluated at each potential starting day, the number of potential schedules increased as testing frequency decreased. Protocol sensitivity was defined for individual testing schedules, where the numerator is the number of testing schedules resulting in at least one positive test and the denominator is the number of testing schedules examined, where a testing schedule is defined as a set of samples from one participant taken at a given frequency. The proportion of “observations” (or sets of samples) with a positive result (at least one positive test in the sampling timeframe) was considered to be the sensitivity of that testing protocol (test and frequency combination).

Sensitivities were considered significantly different at $p < 0.05$. All statistics were calculated using `binom.test` or `glm` in R. All code used in analyses can be found here:

Results

Table 1 shows demographic information for study participants reported here. The majority of participants (30/43, 69.8%) were non-Hispanic white and the average age was 32.3 years (SD 12.8, range: 19, 73). Of the 43 participants, 23 provided 14 days of observations, 10 provided 13 days of observation, and only 3 provided fewer than 10 days of observation.

The estimated daily sensitivities of nasal and saliva RTqPCR and antigen tests relative to the day of first nasal swab viral culture positivity, which was used as a surrogate marker of infectious virus shedding, are shown in **Figure 1** and **Table S1**. For all three tests, daily and status sensitivity peaked during days in which infectious virus shedding was detectable, as would be expected. Antigen test daily sensitivity declined precipitously after infectious virus could no longer be detected in nasal swabs, dropping to 0.238 (95% CI: 0.135, 0.385) within a week after the onset of culture positivity, which was significantly lower ($p < 0.001$) than both nasal and saliva RTqPCR platforms. Nasal and saliva RTqPCR only showed minor decreases in sensitivity during this period, remaining at 0.857 (95% CI: 0.722, 0.933) and 0.690 (95% CI: 0.540, 0.809) after a week, respectively, and were not significantly different from each other ($p = 0.07$).

We also used the viral culture data to measure the status sensitivities of each test before, during, and after viral shedding (**Figure 2**). Prior to the first day of detectable shedding of infectious virus, nasal RTqPCR tests had significantly higher ($p < 0.05$) sensitivity, 0.650 (95%

CI: 0.483, 0.794), than the antigen test (0.375, 95% CI: 0.227, 0.542). The sensitivity of saliva RTqPCR, 0.750 (95% CI: 0.588, 0.873), was not significantly different from that of nasal RTqPCR ($p=0.14$) or antigen ($p=0.07$) prior to the first positive viral culture. On days when the viral culture was positive, there were no significant differences in sensitivity among the three testing modalities ($p>0.2$). After viral culture was no longer positive, the sensitivity of the antigen test (0.454, 95% CI: 0.376, 0.534) was significantly lower ($p<0.001$) than the sensitivity of the saliva (0.847, 95% CI: 0.782, 0.898) or nasal (0.945, 95% CI: 0.898, 0.974) RTqPCR tests.

We next estimated the protocol sensitivities, or how the ability of each of test platform to detect infected individuals was affected by differences in testing frequencies (**Table 2, Figure 3**). In the top panel of **Figure 3**, we show sensitivity to detect infected individuals at any stage of infection. For all three test platforms examined, protocol sensitivity remained >0.98 with testing at least every third day. When applied weekly, protocol sensitivity remained very high for nasal RTqPCR at 0.987 (95% CI: 0.966, 0.996) and for saliva RTqPCR 0.963 (95% CI: 0.936, 0.982), but dropped to only 0.797 (95% CI: 0.747, 0.841) for the antigen test, which was significantly lower than either PCR test ($p<0.001$).

When we compared the abilities of different testing frequencies to identify individuals before or during the period when infectious virus was detectable in nasal samples (**Figure 3, bottom panel**), we observed a clear reduction in protocol sensitivity for all testing modalities when testing frequencies decreased below daily, although the linear trend was not statistically significant ($p>0.05$). The reduction in protocol sensitivity was most pronounced for the antigen test, which dropped to 0.739 (95% CI: 0.634, 0.827) with testing every fourth day. However, both RTqPCR tests were only slightly better with both showing a sensitivity of 0.784 (95% CI: 0.684, 0.865) for nasal and of 0.761 (95% CI: 0.659, 0.846) for saliva.

Discussion

This is the first study to compare the longitudinal performance of rapid antigen and RTqPCR tests with infectious virus shedding through daily testing early during SARS-CoV-2 infection. Our data clearly define how the sensitivities of RTqPCR and antigen tests vary over the course of SARS-CoV-2 infection. Prior to the presumed infectious period (here defined as the period during which infectious virus could be detected in nasal swab samples), the daily sensitivities of nasal and saliva RTqPCR tests were substantially higher than that of the Quidel Sofia SARS Antigen FIA, suggesting that RTqPCR tests will be more effective than antigen tests at identifying infected individuals before they can transmit to others, provided that results reporting is rapid enough.

Both RTqPCR and antigen tests peak in daily and status sensitivities when infectious virus is detectable in nasal swab samples, suggesting that all three modalities can be effective at identifying individuals during the presumed infectious period. After this period, the daily sensitivity of RTqPCR tests decreased gradually, consistent with the dynamics described previously for RTqPCR [10,11]. In contrast, the daily sensitivity of the antigen test declined very quickly, suggesting that this test will be less effective at identifying individuals during later stages of infection. The short duration of antigen positivity may limit diagnosis and contact-tracing efforts in test-limited environments.

Previous studies have suggested that frequent testing would maximize the ability of a given test modality to detect infected individuals at any stage of infection [12–14]. We found that all testing modalities showed >98% protocol sensitivity to detect infection if used at least every three days, which supports that conjecture. However, the results presented here are based

on empirical data, rather than the modeling approaches previously used, and therefore give stronger confidence to these estimates.

Altogether, these data demonstrate the importance of frequent testing regardless of test modality for identifying individuals while they are contagious. It should be noted that while virus culture on nasal swabs represents the best proxy available for infectivity, it is likely imperfect. It is also possible that some samples taken from infectious individuals may have given negative results in the virus culture assay because they were below the limit of detection, especially given that the viral culture samples were subjected to a single freeze/thaw cycle prior to being assayed.

The sensitivities of particular testing protocols presented here assume that individuals will strictly adhere to these testing frequencies over time. This may be more feasible in more closed populations, such as schools or businesses, than in general public health settings where the population is more fluid. However, the results could also be applied at a personal level to assist concerned individuals in determining the best frequency at which to seek out testing. These results should not be applied to interpret the results of a single test outside the context of regular screening.

It should also be noted that participation in this study was limited to faculty, students, and staff of the University of Illinois at Urbana-Champaign, and that the participant population included here was primarily young, non-Hispanic white, and skewed slightly towards males. All infections were either mild or asymptomatic, and no participants were hospitalized for COVID-19. The limited demographic and clinical profiles of our study population must be considered when extending these results to groups with different risk profiles.

Altogether, our results indicate that frequent serial RTqPCR testing with rapid results reporting is the optimal screening strategy for identifying asymptomatic or pre-symptomatic individuals before they can transmit the virus, thus mitigating community spread of SARS-CoV-2. In communities where serial RTqPCR testing with rapid results reporting is not possible, then frequent serial antigen testing (at least every three days or twice weekly) represents the best alternative.

Table Legends:

Table 1: Demographic information on participants enrolled in the COVID detect study

Table 2: Protocol sensitivity of each test platform to detect an infected person during a 14-day testing period, relative to the frequency of testing.

Table S1: Daily sensitivity of each test platform by day relative to the day of first nasal swab viral culture positivity.

Figure legends:

Figure 1: Daily sensitivity of each test platform by day relative to the day of first positive viral culture result. Shaded areas represent the 95% confidence interval around the observed proportion.

Figure 2: Status sensitivity of each test platform relative to viral culture positivity.

Bars indicate the 95% confidence interval around the observed proportion. Pre-positive (n=31) refers to samples taken on days before the first viral culture-positive sample collected from each individual. Positive (n=153) refers to samples taken on days for which viral culture results were positive. Post-positive (n=126) refers to samples taken on days with negative viral culture results that occur after the first positive culture result.

Figure 3: Protocol sensitivity of each test platform to detect an infected person (top) before or during days where nasal samples were viral culture positive or (bottom) at any time, over a 14-day testing period, relative to frequency of testing. Lines indicate 95% confidence interval around the observed proportion.
